Summary

The objective of this work is to determine the chemical mechanisms of solid propellant ignition and deflagration with an emphasis on the decomposition of individual propellant ingredients and on the gas phase reactions of the products of decomposition. A quadrupole mass spectrometer system using quartz microprobes measures species profiles above the surface of the sample during CO_2 laser induced pyrolysis or during laser assisted deflagration of the sample. In addition microthermocouples are used to measure the surface temperature and gas phase temperatures during testing. To complement the experimental studies, chemical kinetic models produced by other researchers are used to model some of the data obtained.

During FY 94, after significant effort to construct the triple quadrupole mass spectrometer (TQMS) and optimize its operational parameters for separation of species at mass 28 (CO, N_2 and C_2H_4) and mass 44 (CO_2, N_2O and CH_3CHO) using laboratory standards, it was successfully applied in RDX tests at different pressures and heat fluxes. Using the full capability of the TQMS, two separate tests to quantify the parent and daughter species allow complete determination of the major species in RDX laser assisted deflagration. In addition to the RDX studies, preliminary studies of oxetane polymers were also performed.

The first task for RDX was to determine the relative contributions of species at mass 28 and 44. Mass 28 was found to consist only of N_2 and CO, with no C_2H_4 present. Throughout the gas-phase, N_2 was generally slightly larger than CO. Mass 44 was exclusively composed of N_2O and CO_2. N_2O constituted all of mass 44 at the surface, but decreased gradually to zero at the end of reaction zones. The opposite was true for CO_2. Some unknown species above mass 40 were found, and they were identified as $HNCO$, NH_2CHO and $HONO$ at mass 43,45 and 47, respectively. Their signal intensities were not negligible near the surface, especially that of $HNCO$.

The RDX results at high heat flux and atmospheric pressure show NO and NO_2 profiles that are in good agreement with the recent measurements of Parr and Hanson-Parr obtained by absorption. However, the TQMS data still show a substantial amount of formaldehyde, based upon the 29 amu peak, while Parr and Hanson-Parr detected none in their study. Therefore, additional RDX studies were performed to determine whether other species were contributing to 29 amu. These studies showed that near the surface another species was contributing to the signal at 29 amu. Further tests to determine the exact structure of the unknown peak at mass 29 will be a priority in the near term.

The effects of heat flux and pressure were also studied for RDX laser-assisted combustion. By increasing heat flux and decreasing pressure, reaction zones were stretched out, but the major reaction pathways of decomposition were found to be unaffected. The primary flame zone was marked by the disappearance of mass 29 and NO_2, and the production of NO, CO, CO_2 and H_2O. In the secondary flame zone, HCN, NO and to a lesser extent N_2O were consumed, and CO_2, N_2, CO, H_2O and H_2 were produced. No evidence of a near surface reaction zone, postulated by Russian researchers, was found very near the surface and preceeding the primary flame zone even at the low pressure and high heat flux condition.

In addition to the RDX tests, experiments were performed to study the parent ions produced by oxetane polymers, BAMO and NMMO. These results show more than fourteen major species over a rather narrow molecular weights from 15 to 45. The presence of so many species at close molecular weights presents a substantial challenge to the TQMS. As a result significant effort will be required to determine the structure of these species using the full capabilities of the TQMS.

Objective

The objective of this effort is to determine the chemical mechanisms of solid propellant ignition and deflagration with an emphasis on the decomposition of individual propellant ingredients and on the gas phase reactions of the products of decomposition. The information gained will be coupled into existing modeling efforts supported by ONR. In this program both solid oxidizers and energetic binders will be studied. A quadrupole mass spectrometer system using quartz microprobes is used to measure species profiles above the surface of the sample during CO2 laser induced pyrolysis or during laser assisted deflagration of the sample. Gas phase temperature profiles are measured with micro-thermocouples no larger than 50 micron.

During the past year a related objective of the program was to bring the (MPMS) system with the triple quadrupole mass spectrometer (TQMS) to a fully operational state. The TQMS can detect and quantify species with similar molecular weights but different compositions, and identify the structure of unknown species. This objective was achieved early in FY 94.

Approach

A schematic diagram of the experimental setup is given in Fig. 1. The energy source of ignition was a high-power CO_2 laser with a maximum continuous wave power of 700W. The laser beam passed through a mask and an expanding lens before entering the test chamber through a KCl window. The size of beam was selected to be about twice that of the sample so that a nearly uniform beam profile could be applied to the surface. The RDX samples were 0.64 cm diameter pellets pressed from RDX powder.

The propellant samples were glued to a small block angled at 45° to the incident laser beam so that the sampling microprobe approached the sample perpendicular to the center of the sample surface. During a test, the sample was pushed toward the sampling probe by a linear positioner to obtain species profiles. A high-quality plexi-glass window was installed on one side of the chamber for video photography of the flame and the RDX pellet. The video was acquired using a CCD video camera with a micro lens; after each test it was used to identify the sampling height, i.e., the distance between the RDX surface and the sampling probe tip. Typically, a magnification of 30 to 40 times was used which produced a spatial resolution of about 20mm for the videos.

The analysis of gaseous species was performed using the microprobe/mass-spectrometer (MPMS) system. The species were sampled by quartz microprobe with an orifice diameter of 20 to 30mm which produced spatial resolution of 100 to 150 mm. The sample gases were drawn through the probe and into the mass spectrometer by a set of turbomolecular pumps

and vacuum pumps and ionized at the ionizer in MS. In early experiments to determine the decomposition species a single quadrupole mass spectrometer was used. In later tests for species profiles the mass spectrometer unit was upgraded to a triple quadrupole mass-spectrometer (TQMS) from Extrel. The TQMS was required for these tests to overcome difficulties in differentiating species with same mass using the single quadrupole mass spectrometer. Differentiating multiple species with the same mass is very difficult with a single quadrupole and requires multiple runs at different ionization energies or the application of a matrix approach to obtaining quantitative data. Using the so-called "daughters" mode of operation of the TQMS, it was possible to identify and differentiate N_2, CO, C_2H_4 at 28-amu, NO, CH_2O at 30-amu, and N_2O, CO_2 at 44-amu as well as possible species at 29-amu.

In the daughter mode of operation, the mass of interest, often referred to as the "parent", is selected in the first quadrupole. The parent ions then enter the second quadrupole (Q2) and are fragmented into smaller species, the "daughters", by the process of collision-induced dissociation (CID) with an inert gas separately supplied into Q2. Argon was used as the collision gas in this study to minimize its contribution to fragmented masses. The daughters, at masses less than their parent, are detected in the third quadrupole. For complex parent ions, some of the daughters might overlap if the parents contain common structures. In the present study, however, at least one unique daughter could be acquired for each parent.

Several methods of calibration were used to obtain the sensitivity coefficients (intensity/concentration) of each species. Most stable species were calibrated directly with the gas mixtures of known concentration. To calibrate water, water vapor was acquired from liquid water which was vaporized by the CO_2 laser. Paraformaldehyde and trioxane, polymeric forms of CH_2O, were used for its calibration. They were also vaporized with the CO_2 laser to obtain gas-phase formaldehyde. Typically the sensitivity factors were repeatable within 10%. The calibration of species for which standards were not readily available, e.g. HCN, were estimated by correlating the signal intensity to that of calibrated species with a similar appearance potential through the ratio of their cross-sections. [1]

For all of the calibrations and in the actual tests, an ionization energy of 22 eV was used to minimize fragmentation of molecules and to get acceptable intensities. However, this setting was still high compared to the ionization energies of 9 -15 eV for most organic compounds, thus some fragments were formed and contributed to the signals at masses other than the parent mass. In such instances, these signals were subtracted from the mass signal of interest.

In reducing the experimental data the measured concentrations were totaled and each concentration was divided by the total to get the mole fractions of the sampled gases. This method of calculating normalized mole fractions eliminates the effect of sample temperature

on the observed signal intensities since the temperature dependence cancels out. This calculation method also cancels out the effect on signal intensity of probe orifice blockage during a test. The measured mole fractions were then used to perform element balances through the reaction zones as a check on the quality of the data.

Summary of Results

This section of the report will provide more details on the three major areas of study for FY 94. They are studies to determine the contributions of various species at 28 and 44 amu as well as 29 amu, experiments to determine the effects of heat flux and pressure on RDX gas-phase structure, and preliminary studies of the oxetane polymer, BAMO/NMMO.

RDX Experimental Studies

Species at 28 and 44 amu

In RDX combustion, possible sources of mass 28 are N_2, CO and C_2H_4. Using the TQMS, these three species could be differentiated and identified in the daughter mode. Q1 was fixed at mass 28 and Q3 was scanned over possible masses of daughters in each species. By this method, N_2 was identified by mass 14 (N), CO was by 12 (C), and C_2H_4 by 15 (CH_3). For C_2H_4, the signal intensities of mass 27 (C_2H_3), 26 (C_2H_2), 25 (C_2H) and 14 (CH_2) should be higher than that of mass 15 (CH_3) because they are easier to create by fragmentation than mass 15 . However, mass 25 to 27 were too near to the parent mass 28 to identify because of the high signal level from the parent, and mass 14 overlapped with the daughter mass from N_2. In the actual experiment, the signal of mass 15 was just above the noise range, thus C_2H_4 appears not to be a major product of RDX. Without C_2H_4 present, N_2, CO were easily distinguished in the daughter mode.

Three possible species could exist at mass 44: N2O, CO2 and CH3CHO. As in the case of mass 28, key daughters were identified during calibration for each of these species: mass 28 (N2) and 30 (NO) for N2O, mass 28 (CO) for CO2, and primarily mass 15 (CH3) and 29 (CHO) for CH3CHO. In the actual experiments, no daughter signals were found except mass 28 and 30 by screening from mass 10 to 40 in the daughter mode, thus CH3CHO was eliminated as a possible product. Actually this result was expected because formation of CH3CHO in RDX combustion requires complex interactions. It is interesting to note that CH3CHO is found, however, in RDX-based composite propellants[2]. The daughter signal at mass 28 can come from N2O and CO2, simultaneously. Therefore. mass 30 was selected exclusively to identify N2O, and CO2 could be easily identified by subtracting the intensity of N2O from the total intensity of mass 44 signal in the parent mode.

The trends of N2O and CO2 versus height from the surface are shown in Figure 2 at three test conditions. N2O constitutes all of mass 44 at the surface without the existence of CO2, but N2O decreases exponentially as the height increased. At the end of reaction zones, all of mass 44 was composed of CO2, one of the final products of combustion. From the profiles of the N2O species, the expansion of reaction zones as heat flux increased and pressure decreased is clearly visible.

Species at high masses 43,45 and 47

Species at masses 43, 45 and 47 were identified in several previous studies and were recognized to have important roles in the gas-phase chemistry of RDX.[3,4,5,6,7] Mass 43 was identified as HNCO, mass 45 as NH_2CHO and mass 47 as HONO. In the present study, the intensities of these species became larger as pressure decreased and heat flux increased, i.e. as the reaction zones expanded. The mole fractions of HNCO at the surface, however, were almost constant in the range of 3.5 % - 4.5 % for all experimental conditions. The sensitivity of HNCO here was estimated by the theory of ionization cross section[1] referred in the experimental section.

Species at 29 amu

Some questions have been raised regarding the mole fraction of CH_2O near the surface of deflagrating RDX obtained from mass 29. The mole fraction of CH_2O has been reported to be almost zero near the surface in other studies.[8,9] In these studies, the ranges of experimental conditions were not too different from those of the present study and therefore experimental conditions cannot explain the differences. Based upon the signal at mass 29 in previos work with the MPMS [10,11], the mole fraction was measured to be about 7 % in 1 atm and 100 W/cm^2, and about 18 % in 0.5 atm and 400 W/cm^2 at the surface. The discrepancy between these results and those of other researchers required careful consideration of possible causes.

Several possible reasons difference related to the probe sampling method were originally considered as possible causes. One of possible reasons was the condensation of some CH_2O in the microprobe or vacuum chamber with subsequent evaporation. Another possible one was that there were other species at mass 29 besides CHO. The second possibility was more reasonable because the microprobe sampling method had problems only in detecting CH_2O/CHO, not any other major product. This possibility supplied the motivation to perform experiments in the daughter mode for the parent at mass 29 and 30.

The results of calibration in daughter mode for NO, CHO and CH_2O at 1 atmosphere are shown in Figure 3. Mass 14 (N) and 16 (O) were detected with the ratio of ~1.65 to 1 for

NO. For CHO, mass 13 (CH) and 12 (C) were identified with the ratio of ~2.4 to 1, and for CH_2O mass 14 (CH_2), 13 (CH) and 12 (C) with the ratio of ~20 : 2.5 :1. In experiments with RDX at 1 atm and 100 W/cm^2, several interesting results were acquired in terms of mass 29 and 30. In Figure 4-(a), daughter masses 14 and 16 were measured for the parent mass 30, and the ratio of mass 14 and 16 was calculated. In the region where the mass 30 is large, the ratio was within the bounds of 1.6 and 1.73. Comparing this ratio to the calibration of Figure 3 suggests that the amount of CH_2O is small or the ratio would deviate from the NO calibration data due to the presence of a strong 14 signal from CH_2O. Based upon these results, the maximum possible mole fraction of CH_2O near the surface was about 3 %. Considering the inevitable fluctuation of signals in calibration and actual experiments in daughter mode of TQMS, it is possible that CH_2O does not exist near the surface at this test condition. More experiments will be performed at other conditions to ascertain whether CH_2O is present.

Results from actual experiments at mass 29 and 30 are also given in Figure 4. From the calibration of CHO, mass 13 and 12 were identified as the only possible daughters if only CHO existed at mass 29. In the real test at 1atm and 100 W/cm^2, however, a large signal at mass 14 was detected near the surface. Possible chemical species should be just CH_2 or N for mass 14, which could come from other parent masses such as H_2CNH or C_2H_5, a radical which would have to come from fragmentation of a larger species in the ionizer. C_2H_5 was eliminated as a possible species because mass 15 (CH_3) is formed in its fragmentation, and mass 15 was not detected in daughter mode. Therefore, the most likely species appears to be something containing N, such as H_2CNH. The fragment of mass 14 is highly possible from H_2CNH, because CID is strong enough to break multiple bonds and thus no preference was identified in the fragmentation of parent ions[1]. However, while the radical H_2CN has already been suggested as an important intermediate species to form HCN[3], H_2CNH has never been reported in other experiments. Thus any firm conclusion about mass 29 must be delayed until more decisive evidence can be found for the existence of H_2CNH.

Effects of Heat Flux and Pressure on RDX Gas-phase Structure

Measurements of major species at the condition of 1 atm and 100 W/cm^2 are shown in Figure 5. Several experiments were actually conducted at this condition to increase the resolution of sampling. Increasing resolution was achieved by changing the starting height of sampling probe, because the quartz microprobes were found not to withstand more than 400msec outside flame zones without melting. Figure 6 is a combination of two results with different starting heights; the results were cross-checked with other results at same condition to validate measured mole fractions.

Decomposition chemistry in the gas-phase starts by the disappearance of mass of 29 and NO_2 in the primary flame zone very near the surface. Primary products of this consumption were H_2O, NO, CO and CO_2. H_2 was relatively inert in this zone. The existence of N_2 from the surface should not be overlooked. Its production was almost unaffected by the change of pressure and heat flux.

The secondary flame zone has been characterized by the consumption of NO and HCN, and by the production of CO_2, N_2, CO, H_2O and H_2. The consumption of N_2O produces N_2 in this zone. At approximately 3mm from the surface, the reaction zone came to the post-flame region at this condition. In the region, major products were identified as CO_2, N_2, CO, H_2O, H_2 and small amount of NO (~ 2 %). Small signal intensities of N_2O, NO_2, HCN were noticed in this region, but they are in the range of noise fluctuation.

In Figure 6, the species profiles are shown for a heat flux of 400 W/cm^2 at 1atm. Chemical structures of flame were similar to those at 100 W/cm^2. However, the end of the secondary flame zone expanded to more than 5mm from the surface based upon the profile of NO. At the surface, mole fractions of NO2 and HCN increased and that of N2O decreased relative to the lower heat flux case, because the N-N bond scission was preferred at the high heat flux condition. The thickness of primary reaction zone, indicated by the NO2 profile, was not changed as heat flux increases. This trend was also observed for other species in Figure 6 and shows that the change of heat flux does not have much effect on the chemical mechanisms near the surface. From the profiles of major species, especially NO, N2O and HCN, the secondary flame zone was also stretched substantially compared with that at 100 W/cm^2. Even at 5mm from the surface, NO and HCN were still being consumed.

The species profiles in the gas-phase at the condition of 0.5atm and 400 W/cm^2 are presented in Figure 7. Because effects of lower pressure and higher heat flux were added in the experiment, the reaction zone near the surface was highly stretched. Therefore, the secondary flame zone did not begin until about at 4.5 mm from the surface, as indicated by the consumption of NO and HCN. The existence of another reaction zone very near the surface, postulated by Korobeinichev at al.[8] is not evident in the species profiles of products NO_2, HCN and CH_2O. Mole fractions of these species showed practically no change near the surface, suggesting that the additional effect of lowering pressure from 1 to 0.5 atm was only stretching the reaction zone near the surface. The mole fraction of mass 29 and NO_2 increased and HCN decreased with little change in N_2O at the surface in the comparison to results of 1 and 0.5 atm.

The primary flame zone was stretched up to 3 - 3.5 mm and secondary flame zone reactions started at 4 - 4.5 mm. HCN and NO were identified to be the only species produced in the primary flame zone again. At this condition, the primary reaction thickness increased

to ~4 mm from ~0.5 mm of previous two conditions. This result shows that pressure is the primary means to expand reaction zones near the surface. Reaction mechanisms appear to be quite the same as that of previous two conditions, thus stretching the reaction zones by increasing heat flux and decreasing pressure appear to be a valid means to study the gas-phase.

Modeling of the high heat flux results is underway and the results are targeted for a refereed journal publication.

Oxetane Polymer Studies

In addition to the RDX tests, experiments were performed to study the parent ions produced by oxetane polymers, BAMO and NMMO. These results show more than fourteen major species over a rather narrow molecular weights from 15 to 45. The presence of so many species at close molecular weights presents a substantial challenge to the TQMS. As a result significant effort will be required to determine the structure of these species using the daughters mode. Once these species have been identified, the polymer will be used in sandwich studies.

Future Work

MPMS studies

During the next fiscal year efforts will concentrate on the identification of the unknown species at 29 amu in RDX and the work on RDX will be prepared for submission to a refereed journal. Following the completion of the RDX studies, experiments to identify the species produced by the oxetane polymers will be carried out. Also preliminary "sandwich" studies will be performed.

Microthermocouples

Recently Professor Zenin of Russian Institute of Chemical Physics visited Penn State and presented a series of seminars on his thermocouple methods. These methods will be adapted to be used in the MPMS facility so that temperature profiles can be obtained for in the condensed and gas-phases of RDX.

RDX Modeling Studies

In the very near future the RDX results at 400 W/cm^2 will be combined with the temperature profile of Parr and Hanson-Parr and used to validate the kinetics model of Yetter and Dryer with the CHEMKIN code.
